

TITLE

Sensor for capacitively measuring the distance to an object

DESCRIPTION5 Technical Field

The present invention relates to sensors, and in particular to sensors that can be used for capacitively measuring the distance to either a stationary or passing object.

10 Background Art

In many industrial measurement applications there is a need for a sensor that can be used at high operating temperatures to measure the distance to either a stationary or passing object. A typical application is the  
15 measurement of clearance between the tip of a gas turbine engine blade and the surrounding casing. In this situation the operating temperature of the sensor can reach 1500°C. Other applications including molten metal and molten glass level measurement, for example, have similar operating  
20 temperature requirements.

United States Patent 5,760,593 (BICC plc) describes a conventional sensor having a metal or metal-coated ceramic electrode that couples capacitively with the stationary or  
25 passing object. The electrode is connected directly to the centre conductor of a standard triaxial transmission cable and is surrounded by a metal shield and an outer housing. The metal shield and the outer housing are connected directly to the intermediate conductor and the outer

## SUBSTITUTE SPECIFICATION

conductor of the triaxial transmission cable respectively.  
Electrical insulation is provided between the electrode and  
the shield and also between the shield and the housing.  
The insulation can be in the form of machined ceramic  
5 spacers or deposited ceramic layers.

One problem with these conventional sensors is that they  
utilise an alternating combination of metal and ceramic  
materials. As the operating temperature of the sensor  
10 increases, the metal components tend to expand more than  
the ceramic components. This often results in stress  
fractures forming in the ceramic spacers or layers, which  
reduce their electrical performance and may even result in  
the disintegration or de-lamination of the ceramic  
15 components. Not only does this cause the sensor to fail  
electrically, but the disintegration or de-lamination of  
the ceramic components also allows the metal components to  
vibrate and this can result in the mechanical failure of  
the complete sensor assembly.

20 Gas turbine engine manufacturers now require an operating  
lifetime of at least 20,000 hours for sensors that are to  
be fitted to production models. Although conventional  
sensors have been successfully used at high operating  
25 temperatures for short periods of time, it is unlikely that  
they will ever be able to meet the required operating  
lifetime because of the inherent weakness of the sensor  
assembly caused by the different thermal expansion  
properties of the metal and ceramic components.

## SUBSTITUTE SPECIFICATION

A further problem is the way in which the electrode, shield and outer housing are connected to the transmission cable. With conventional sensor designs, the conductors of the transmission cable are directly connected to the electrode, shield and outer housing at a high temperature region (i.e. a part of the sensor that reaches an elevated temperature in use). Many types of transmission cables (in particular those where the conductors are insulated using mineral compounds) cannot be used at high temperatures and often fail after a short period of time. Furthermore, some conventional sensors do not have a hermetic seal between the transmission cable and the rest of the sensor assembly. This can allow moisture to penetrate the sensor assembly and reduce the performance of the sensor.

Summary of the Invention

The present invention provides a sensor for capacitively measuring the distance to a stationary or passing object, comprising an electrically conductive ceramic electrode for capacitively coupling with the object, and a housing that substantially surrounds the electrode.

Because the electrode is formed from an electrically conductive ceramic, the sensor can be used at higher operating temperatures than conventional sensors that use metal or metal-coated ceramic electrodes. The housing is preferably formed from an electrically non-conductive

## SUBSTITUTE SPECIFICATION

ceramic and may be of any suitable shape or size to suit the installation requirements.

To isolate the electrode from any external electrical interference, the sensor can further comprise a shield that substantially surrounds the electrode and is electrically isolated from the electrode by an insulating layer. The shield is can be formed from a solid piece of electrically conductive ceramic. However, the shield can also be a thin electrically conductive ceramic layer that is deposited onto the insulating layer using conventional deposition techniques. The use of a deposited ceramic layer greatly simplifies both the design of the sensor and subsequent assembly. The shield can also be a thin electrically conductive ceramic or metallic layer that is deposited onto the inside surface of the outer housing using conventional deposition techniques. The insulating layer is preferably formed as a machined electrically non-conductive ceramic spacer. The use of a ceramic layer with a similar coefficient of thermal expansion to both the insulating layer and the housing means that the coating will not tend to delaminate in service, which is possible with metallic coatings which have different thermal expansion characteristics.

The electrically conductive ceramic and the non-electrically conductive ceramic are preferably selected to have similar thermal expansion coefficients so that the sensor assembly remains virtually stress free at high

## SUBSTITUTE SPECIFICATION

operating temperatures. The electrode and the shield can be formed from SiC and the insulating layer and the housing can be formed from SiN, for example. The electrode, shield and housing can be bonded together using standard diffusion bonding or vacuum braising methods to form an integral ceramic structure. The bonding provides a hermetic seal between the components that prevents the ingress of moisture into the sensor assembly and the transmission cable.

10

The sensor can have a "captive" design so that if any of the ceramic components do fail for any reason then they are retained within the overall sensor assembly.

15 Instead of joining the conductors of the transmission cable directly to the electrode and the housing at a high temperature region of the sensor, the conductors are preferably connected to electrically conductive bridges that are in turn connected to the electrode and the housing. The electrically conductive bridges extend away from the front face of the electrode (i.e. the face that faces toward the object in use) so that the connection between the conductors and the electrically conductive bridges takes place at a low temperature region at the rear of the sensor.

25

If the sensor does not include a shield then a coaxial transmission cable having a central conductor and an outer conductor can be used. The central conductor is preferably

## SUBSTITUTE SPECIFICATION

connected to the electrode by means of a first electrically  
conductive bridge and the outer conductor is preferably  
connected to the housing by means of a second electrically  
conductive bridge. The first electrically conductive  
5 bridge preferably passes through apertures provided in the  
housing and the second electrically conductive bridge.

The connection between the conductors and the electrically  
conductive bridges is preferably made using an adapter.  
10 The adapter can be shaped to accommodate a variety of  
different types and diameters of transmission cable.  
Furthermore, the adapter can connect the conductors to the  
electrically conductive bridges in a number of different  
orientations depending on the installation requirements of  
15 the sensor. For example, the conductors can be connected  
such that the transmission cable extends away from the  
front face of the electrode substantially parallel to the  
electrically conductive bridges. Alternatively, the  
conductors can be connected such that the transmission  
20 cable extends substantially at right angles to the  
electrically conductive bridges. Other orientations are  
also possible.

If the sensor does include a shield then a triaxial  
25 transmission cable having a central conductor, an  
intermediate conductor and an outer conductor can be used.  
The central conductor is preferably connected to the  
electrode by means of a first electrically conductive  
bridge, the outer conductor is preferably connected to the

## SUBSTITUTE SPECIFICATION

housing by means of a second electrically conductive bridge and the intermediate conductor is preferably connected to the shield by means of a third electrically conductive bridge. The first electrically conductive bridge preferably  
5 passes through apertures provided in the insulating layer, the shield, the third electrically conductive bridge, the housing and the second electrically conductive bridge. Similarly, the third electrically conductive bridge preferably passes through aperture provided in the housing  
10 and the second electrically conductive bridge.

The electrically conductive bridges can be formed from metal or electrically conductive ceramic and are preferably connected to the electrode, housing and shield using  
15 standard diffusion bonding or vacuum braising methods. Although it is generally preferred that the bridges are formed from electrically conductive ceramic, metal bridges can be used because they are connected to the electrode, shield and housing at an intermediate  
20 temperature region and so do not suffer significantly from the problems of thermal expansion. The electrically conductive bridges can be made in any size or shape depending on the design and installation requirements of the sensor.

25 An adapter is preferably provided to connect the second and third electrically conductive bridges to the outer and intermediate conductors, as described above.

## SUBSTITUTE SPECIFICATION

The second electrically conductive bridge can substantially surround the housing such that it extends a part or all of the way along the side face of the housing. However, it is generally preferred that the shield, the insulating layer, the housing and the second electrically conductive bridge do not extend along the front face of the electrode.

The use of electrically conductive bridges means that the sensor assembly can be manufactured and tested before it is connected to the transmission cable using an adaptor. This is not possible with conventional sensors where the transmission cable has to be directly connected to the electrode, housing and shield during the assembly process.

The electrically conductive bridges can also be used with conventional sensors and those that utilise metal/ceramic and plastics/metal components.

15

With reference to Figure 1, a "coaxial" sensor 1 has a cylindrical electrode 2 formed from an electrically conductive ceramic material. A front face 3 of the electrode 2 is directed toward a stationary or passing  
20 object (not shown). The electrode 2 is located within and bonded to a housing 4 formed from an electrically non-conductive ceramic material. The electrically conductive and electrically non-conductive ceramic materials are chosen so that they have a similar thermal expansion  
25 coefficient and the sensor 1 remains virtually stress free at high operating temperatures.

A front bridge piece 5 is located within the housing 4 and is bonded to a rear face 6 of the electrode 2. A rear

## SUBSTITUTE SPECIFICATION

bridge piece 7 is bonded to a rear face 8 of the housing 4. The front bridge piece 5 passes through apertures provided in the housing 4 and the rear bridge piece 7 to extend beyond the rear bridge piece. The aperture provided in the rear bridge piece 7 is wider than the front bridge piece 5 so that the two bridge pieces are separated by an annular air gap 9.

The front and rear bridge pieces 5 and 7 are connected to the two concentric conductors of a mineral insulated coaxial transmission cable 20 as shown in Figure 2. The transmission cable 20 has a central conductor 21 and an outer conductor 22 separated by a mineral insulating layer 23. An electrically conductive cylindrical adaptor 30 is used to join the front bridge piece 5 to the central conductor 21 at a common interface 24 and the rear bridge piece 7 to the outer conductor 22. Alternatively, the electrically conductive adaptor 40 shown in Figure 3 can be used. The adaptor 40 is designed to receive the transmission cable 20 such that central and outer conductors 21 and 22 are connected substantially at right angles to the front and rear bridge pieces 5 and 7 and the centreline of the sensor 1.

It will be readily appreciated that the use of the adaptor 30, 40 means that the "coaxial" sensor 1 can be fully assembled and tested before being connected to the transmission cable 20. It also means that the front and rear bridges pieces 5 and 7 and the central and outer

## SUBSTITUTE SPECIFICATION

conductors 21 and 22 are connected together at a low-temperature region of the sensor 1.

5 In Figures 1 to 3, the rear bridge piece 7 is formed on the rear face 8 of the housing 4 only. However, the rear bridge piece 7 can also extend along part or all of the side face 10 of the housing 4 as shown in Figures 4a and 4b.

10 In operation, the "coaxial" sensor 1 is mounted so that the front face 3 of the electrode 2 is directed toward the stationary or passing object. The electrode 2 is energised by a signal transmitted along the central conductor 21 of the transmission cable 20 so that it capacitively couples  
15 with the stationary or passing object. The changes in the capacitance detected by the electrode 2 are transmitted back along the central conductor 21 as voltage signals and converted into distance measurements so that the distance  
20 between the electrode and the stationary or passing object can be calculated.

With reference to Figure 5, a "triaxial" sensor 100 has a cylindrical electrode 102 formed from an electrically conductive ceramic material. A front face 103 of the  
25 electrode 102 is directed toward a stationary or passing object (not shown). The electrode 102 is located within and bonded to an electrically non-conductive ceramic spacer 104. The electrode 102 and the spacer 104 are located within and bonded to an electrically conductive ceramic

## SUBSTITUTE SPECIFICATION

shield 105 which isolates the electrode from any external electrical interference. The shield 105 is located within and bonded to a housing 106 formed from an electrically non-conductive ceramic material. The electrically  
5 conductive and electrically non-conductive ceramic materials are chosen so that they have a similar thermal expansion coefficient.

A front bridge piece 107 is bonded to a rear face 108 of  
10 the electrode 102. An intermediate bridge piece 109 is bonded to a rear face 110 of the shield 105. A rear bridge piece 111 is bonded to a rear face 112 of the housing 106. The intermediate bridge piece 109 passes through apertures provided in the housing 106 and the rear bridge piece 111  
15 to extend beyond the rear bridge piece. The front bridge piece 107 passes through apertures provided in the spacer 104, the shield 105, the intermediate bridge piece 109 and the rear bridge piece 111 to extend beyond the intermediate bridge piece and the rear bridge piece. The aperture  
20 provided in the rear bridge piece 111 is wider than the intermediate bridge piece 109 so that the two bridge pieces are separated by an annular air gap 113. Similarly, the aperture provided in the intermediate bridge piece 109 is wider than the front bridge piece 107 so that the two  
25 bridge pieces are separated by an annular air gap 114.

With reference to Figure 5a, the electrically conductive ceramic shield 105 shown in Figure 5 can be replaced by a thin electrically conductive ceramic layer 105a that is

## SUBSTITUTE SPECIFICATION

deposited onto the spacer 104 using conventional techniques. The ceramic layer 105a contacts the intermediate bridge piece and functions in exactly the same way as the shield 105. The use of a thin deposited ceramic layer 105a allows the size of the spacer 104 to be increased with an improvement in the strength and robustness of the sensor. The resulting sensor is also easier to assemble because to the simplification in the overall sensor design.

10

With reference to Figure 5b, the electrically conductive ceramic shield 105 shown in Figure 5 can be replaced by a thin electrically conductive ceramic or metallic layer 105b that is deposited onto the inside surface of the electrically non-conductive outer housing 106 using conventional deposition techniques. The conductive layer 105b contacts the intermediate bridge piece and functions in exactly the same way as the shield 105. The use of a thin deposited conductive layer 105b allows the size of the spacer to be increased with an improvement in the performance of the sensor. The sensor is also easier to assemble because of the simplification in the overall sensor design.

15

The front, intermediate and rear bridge pieces 107, 109 and 111 are connected to the three concentric conductors of a mineral insulated triaxial transmission cable 50 as shown in Figure 6. The transmission cable 50 has a central conductor 51, an intermediate conductor 52 and an outer

20

25

## SUBSTITUTE SPECIFICATION

conductor 53 separated by mineral insulating layers 54. An electrically conductive cylindrical adaptor 60 is used to join the front bridge piece 107 to the central conductor 51 at a common interface 55, the intermediate bridge piece 109 to the intermediate conductor 52 and the rear bridge piece 111 to the outer conductor 53. Alternatively, the electrically conductive adaptor 70 shown in Figure 7 can be used. The adaptor 70 is designed to receive the transmission cable 50 such that the central, intermediate and outer conductors 51, 52 and 53 are connected substantially at right angles to the front, intermediate and rear bridge pieces 107, 109 and 111 and the centreline of the sensor 100.

The "triaxial" sensor 100 has the same technical advantages and may operate in the same way as the "coaxial" sensor 1 described above. It will be readily appreciated that different measurement electronics can be used with the "coaxial" and "triaxial" sensors.
